

Embedded Linux System Development

STM32MP1 variant

Practical Labs

<https://bootlin.com>

May 18, 2021

About this document

Updates to this document can be found on <https://bootlin.com/doc/training/embedded-linux-4d>.

This document was generated from LaTeX sources found on <https://github.com/bootlin/training-materials>.

More details about our training sessions can be found on <https://bootlin.com/training>.

Corrections, suggestions, contributions and translations are welcome!

Training setup

Download files and directories used in practical labs

Install lab data

For the different labs in this course, your instructor has prepared a set of data (kernel images, kernel configurations, root filesystems and more). Download and extract its tarball from a terminal:

```
$ cd
$ wget https://bootlin.com/doc/training/embedded-linux-4d/embedded-linux-4\
  d-labs.tar.xz
$ tar xvf embedded-linux-4d-labs.tar.xz
```

Lab data are now available in an `embedded-linux-4d-labs` directory in your home directory. This directory contains directories and files used in the various practical labs. It will also be used as working space, in particular to keep generated files separate when needed.

You are now ready to start the real practical labs!

Install extra packages

Feel free to install other packages you may need for your development environment. In particular, we recommend to install your favorite text editor and configure it to your taste. The favorite text editors of embedded Linux developers are of course *Vim* and *Emacs*, but there are also plenty of other possibilities, such as Visual Studio Code¹, *GEdit*, *Qt Creator*, *CodeBlocks*, *Geany*, etc.

It is worth mentioning that by default, Ubuntu comes with a very limited version of the `vi` editor. So if you would like to use `vi`, we recommend to use the more featureful version by installing the `vim` package.

More guidelines

Can be useful throughout any of the labs

- Read instructions and tips carefully. Lots of people make mistakes or waste time because they missed an explanation or a guideline.
- Always read error messages carefully, in particular the first one which is issued. Some people stumble on very simple errors just because they specified a wrong file path and didn't pay enough attention to the corresponding error message.
- Never stay stuck with a strange problem more than 5 minutes. Show your problem to your colleagues or to the instructor.
- You should only use the `root` user for operations that require super-user privileges, such as: mounting a file system, loading a kernel module, changing file ownership, configuring

¹This tool from Microsoft is Open Source! To try it on Ubuntu: `sudo snap install code --classic`

the network. Most regular tasks (such as downloading, extracting sources, compiling...) can be done as a regular user.

- If you ran commands from a root shell by mistake, your regular user may no longer be able to handle the corresponding generated files. In this case, use the `chown -R` command to give the new files back to your regular user.

Example: `$ chown -R myuser.myuser linux/`

Building a cross-compiling toolchain

Objective: Learn how to compile your own cross-compiling toolchain for the uClibc C library

After this lab, you will be able to:

- Configure the *crosstool-ng* tool
- Execute *crosstool-ng* and build up your own cross-compiling toolchain

Setup

Go to the `$HOME/embedded-linux-4d-labs/toolchain` directory.

Install needed packages

Install the packages needed for this lab:

```
$ sudo apt install build-essential git autoconf bison flex texinfo help2man gawk \
  libtool-bin libncurses5-dev
```

Getting Crosstool-ng

Let's download the sources of Crosstool-ng, through its git source repository, and switch to a commit that we have tested:

```
$ git clone https://github.com/crosstool-ng/crosstool-ng.git
$ cd crosstool-ng/
$ git checkout 79fcfa17
```

Building and installing Crosstool-ng

We can either install Crosstool-ng globally on the system, or keep it locally in its download directory. We'll choose the latter solution. As documented at <https://crosstool-ng.github.io/docs/install/#hackers-way>, do:

```
$ ./bootstrap
```

You can continue:

```
$ ./configure --enable-local
$ make
```

Then you can get Crosstool-ng help by running

```
$ ./ct-ng help
```

Configure the toolchain to produce

A single installation of Crosstool-ng allows to produce as many toolchains as you want, for different architectures, with different C libraries and different versions of the various components.

Crosstool-ng comes with a set of ready-made configuration files for various typical setups: Crosstool-ng calls them *samples*. They can be listed by using `./ct-ng list-samples`.

We will load the Cortex A5 sample, as Crosstool-ng doesn't have any sample for Cortex A7 yet. Load it with the `./ct-ng` command.

Then, to refine the configuration, let's run the `menuconfig` interface:

```
$ ./ct-ng menuconfig
```

In Path and misc options:

- Change Maximum log level to see to DEBUG (look for LOG_DEBUG in the interface, using the / key) so that we can have more details on what happened during the build in case something went wrong.

In Target options:

- Set Emit assembly for CPU (ARCH_CPU) to cortex-a7.
- Set Use specific FPU (ARCH_FPU) to vfpv4.

In Toolchain options:

- Set Tuple's vendor string (TARGET_VENDOR) to training.
- Set Tuple's alias (TARGET_ALIAS) to arm-linux. This way, we will be able to use the compiler as arm-linux-gcc instead of arm-training-linux-uclibcgnueabihf-gcc, which is much longer to type.

In C-library:

- If not set yet, set C library to uClibc (LIBC_UCLIBC)
- Keep the default version that is proposed
- If needed, enable Add support for IPv6 (LIBC_UCLIBC_IPV6)², Add support for WCHAR (LIBC_UCLIBC_WCHAR) and Support stack smashing protection (SSP) (LIBC_UCLIBC_HAS_SSP)

In C compiler:

- Make sure that C++ (CC_LANG_CXX) is enabled

In Debug facilities, disable every option, except `strace` (DEBUG_STRACE), with default settings. Some of these options will be useful in a real toolchain, but in our labs, we will do debugging work with another toolchain anyway. `strace` is an exception as we will use it earlier. Hence, not compiling debugging features here will reduce toolchain building time.

Explore the different other available options by traveling through the menus and looking at the help for some of the options. Don't hesitate to ask your trainer for details on the available options. However, remember that we tested the labs with the configuration described above. You might waste time with unexpected issues if you customize the toolchain configuration.

² That's needed to use the toolchain in Buildroot, which only accepts toolchains with IPv6 support

Produce the toolchain

Nothing is simpler:

```
$ ./ct-ng build
```

The toolchain will be installed by default in `$HOME/x-tools/`. That's something you could have changed in Crosstool-ng's configuration.

And wait!

Known issues

Source archives not found on the Internet

It is frequent that Crosstool-ng aborts because it can't find a source archive on the Internet, when such an archive has moved or has been replaced by more recent versions. New Crosstool-ng versions ship with updated URLs, but in the meantime, you need work-arounds.

If this happens to you, what you can do is look for the source archive by yourself on the Internet, and copy such an archive to the `src` directory in your home directory. Note that even source archives compressed in a different way (for example, ending with `.gz` instead of `.bz2`) will be fine too. Then, all you have to do is run `./ct-ng build` again, and it will use the source archive that you downloaded.

Testing the toolchain

You can now test your toolchain by adding `$HOME/x-tools/arm-training-linux-uclibcgnueabi/hf/bin/` to your `PATH` environment variable and compiling the simple `hello.c` program in your main lab directory with `arm-linux-gcc`:

```
$ arm-linux-gcc -o hello hello.c
```

You can use the `file` command on your binary to make sure it has correctly been compiled for the ARM architecture.

Did you know that you can still execute this binary from your x86 host? To do this, install the QEMU user emulator, which just emulates target instruction sets, not an entire system with devices:

```
$ sudo apt install qemu-user
```

Now, try to run QEMU ARM user emulator:

```
$ qemu-arm hello
/lib/ld-uClibc.so.0: No such file or directory
```

What's happening is that `qemu-arm` is missing the shared C library (compiled for ARM) that this binary uses. Let's find it in our newly compiled toolchain:

```
$ find ~/x-tools -name ld-uClibc.so.0
/home/tux/x-tools/arm-training-linux-uclibcgnueabi/hf/
arm-training-linux-uclibcgnueabi/hf/sysroot/lib/ld-uClibc.so.0
```

We can now use the `-L` option of `qemu-arm` to let it know where shared libraries are:

```
$ qemu-arm -L ~/x-tools/arm-training-linux-uclibcgnueabihf/\
  arm-training-linux-uclibcgnueabihf/sysroot hello
```

Hello world!

Cleaning up

Do this only if you have limited storage space. In case you made a mistake in the toolchain configuration, you may need to run `Crosstool-ng` again, keeping generated files would save a significant amount of time.

To save about 11 GB of storage space, do a `./ct-ng clean` in the `Crosstool-NG` source directory. This will remove the source code of the different toolchain components, as well as all the generated files that are now useless since the toolchain has been installed in `$HOME/x-tools`.

Bootloader - U-Boot

Objectives: Set up serial communication, compile and install the U-Boot bootloader, use basic U-Boot commands, set up TFTP communication with the development workstation.

As the bootloader is the first piece of software executed by a hardware platform, the installation procedure of the bootloader is very specific to the hardware platform. There are usually two cases:

- The processor offers nothing to ease the installation of the bootloader, in which case the JTAG has to be used to initialize flash storage and write the bootloader code to flash. Detailed knowledge of the hardware is of course required to perform these operations.
- The processor offers a monitor, implemented in ROM, and through which access to the memories is made easier.

The STM32MP1 SoC, falls into the second category. The monitor integrated in the ROM reads the SD card to search for a valid bootloader (the boot mode is actually configurable via a few input pins). In case no bootloader is found, it will operate in a fallback mode, that will allow to use an external tool to reflash some executable through USB. Therefore, either by using an MMC/SD card or that fallback mode, we can start up an STM32MP1-based board without having anything installed on it.

Setting up serial communication with the board

Plug the USB-A to micro USB-B cable on the Discovery board. There is only one micro USB port on the board, it is CN11, also named ST-LINK. This is a debug interface and exposes multiple debugging interfaces, including a serial interface. When plugged in your computer, a serial port should appear, `/dev/ttyACM0`.

You can also see this device appear by looking at the output of `dmesg`.

To communicate with the board through the serial port, install a serial communication program, such as `picocom`:

```
$ sudo apt install picocom
```

You also need to make your user belong to the `dialout` group to be allowed to write to the serial console:

```
$ sudo adduser $USER dialout
```

Important: for the group change to be effective, you have to *completely log out* from your session and log in again (no need to reboot). A workaround is to run `newgrp dialout`, but it is not global. You have to run it in each terminal.

Run `$ picocom -b 115200 /dev/ttyACM0`, to start serial communication on `/dev/ttyACM0`, with a baudrate of 115200.

If you wish to exit `picocom`, press `[Ctrl][a]` followed by `[Ctrl][x]`.

U-Boot setup

The boot process is done in two steps with the ROM monitor trying to execute a first piece of software, called *fsbl*, from its internal SRAM, that will initialize the DRAM, a second program, *ssbl* that will in turn load Linux and execute it.

In our case, both programs are provided by U-Boot.

Download U-Boot:

```
$ git clone https://gitlab.denx.de/u-boot/u-boot.git
$ cd u-boot
$ git checkout v2021.01
```

Get an understanding of U-Boot's configuration and compilation steps by reading the README file, and specifically the *Building the Software* section.

Basically, you need to:

1. Specify the cross-compiler prefix (the part before `gcc` in the cross-compiler executable name):

```
$ export CROSS_COMPILE=arm-linux-
```

2. Run `$ make <NAME>_defconfig`, where the list of available configurations can be found in the `configs/` directory. There are three flavors of the `stm32mp15` configuration: two to boot using secure boot and a basic one (`stm32mp15_basic`). This is the one we will use.
3. Now that you have a valid initial configuration, you can now run `$ make menuconfig` to further edit your bootloader features.

- In the `SPL / TPL` submenu, disable `Support an environment`, as SPL will jump to the second stage bootloader U-Boot, and not directly to Linux.
- In the `Environment` submenu, we will configure U-Boot so that it stores its environment inside a file called `uboot.env` in an ext4 filesystem:
 - `Disable Environment is not stored`. We want changes to variables to be persistent across reboots
 - `Enable Environment is in a EXT4 filesystem`. Disable all other options for environment storage (e.g. MMC, SPI, UBI)
 - `Name of the block device for the environment: mmc`
 - `Device and partition for where to store the environment in EXT4: 0:4`
 - `Name of the EXT4 file to use for the environment: /uboot.env`
- In the `Device Drivers → Watchdog Timer Support` submenu, disable `IWDG watchdog driver for STM32 MP's family`, so that U-Boot doesn't start the watchdog.

4. In recent versions of U-Boot and for some boards, you will need to have the Device Tree compiler:

```
$ sudo apt install device-tree-compiler
```

- Finally, run `$ make DEVICE_TREE=stm32mp157a-dk13`, which will build U-Boot. The `DEVICE_TREE` variable specifies the specific Device Tree that describes our hardware board, in our case the STM32MP1 Discover Kit 1. Alternatively, if you wish to run just `make`, specify our board's device tree name on Device Tree Control → Default Device Tree for DT Control option.

Flashing U-Boot

The ROM monitor will look for the first stage bootloader in a partition named `fsbl1`. If it cannot find a valid bootloader in this partition, it will then try to load it from a partition named `fsbl2`. This first stage bootloader (in our case the U-Boot SPL) will load the second bootloader (U-Boot itself) from the partition named `ssbl`. Finally, U-Boot will store its environment in the fourth partition, which we'll name `bootfs`.

So, as far as bootloaders are concerned, the SD card partitioning will look like:

Number	Start	End	Size	File system	Name	Flags
1	2048s	4095s	2048s		fsbl1	
2	4096s	6143s	2048s		fsbl2	
3	6144s	10239s	4096s		ssbl	
4	10240s	131071s	120832s		bootfs	

Plug the SD card your instructor gave you on your workstation. Type the `dmesg` command to see which device is used by your workstation. In case the device is `/dev/mmcblk0`, you will see something like

```
[46939.425299] mmc0: new high speed SDHC card at address 0007
[46939.427947] mmcblk0: mmc0:0007 SD16G 14.5 GiB
```

The device file name may be different (such as `/dev/sdb` if the card reader is connected to a USB bus (either internally or using a USB card reader)).

In the following instructions, we will assume that your SD card is seen as `/dev/mmcblk0` by your PC workstation.

Type the `mount` command to check your currently mounted partitions. If SD partitions are mounted, unmount them:

```
$ sudo umount /dev/mmcblk0p*
```

Then, clear possible SD card contents remaining from previous training sessions (only the first megabytes matter):

```
$ sudo dd if=/dev/zero of=/dev/mmcblk0 bs=4k count=200
```

Now, let's use the `parted` command to create the partitions that we are going to use:

```
$ sudo parted /dev/mmcblk0
```

The ROM monitor handles *GPT* partition tables, let's create one:

```
(parted) mklabel gpt
```

Then, the 4 partitions are created with:

³You can speed up the compiling by using the `-jX` option with `make`, where `X` is the number of parallel jobs used for compiling. Twice the number of CPU cores is a good value.

```
(parted) mkpart fsbl1 0% 4095s
(parted) mkpart fsbl2 4096s 6143s
(parted) mkpart ssbl 6144s 10239s
(parted) mkpart bootfs 10240s 131071s
```

You can verify everything looks right with:

```
(parted) unit s
(parted) print
```

Once done, quit:

```
(parted) quit
```

Now, format the boot partition as an ext2 filesystem. This is where U-Boot saves its environment:

```
$ sudo mkfs.ext2 -L boot /dev/mmcblk0p4
```

The U-Boot SPL is *fsbl*. Write it in both fsbl partitions:

```
$ sudo dd if=spl/u-boot-spl.stm32 of=/dev/mmcblk0p1 bs=1M conv=fdatasync
$ sudo dd if=spl/u-boot-spl.stm32 of=/dev/mmcblk0p2 bs=1M conv=fdatasync
```

Then flash *ssbl*, this is the main U-Boot binary:

```
$ sudo dd if=u-boot.img of=/dev/mmcblk0p3 bs=1M conv=fdatasync
```

Testing U-Boot

Insert the SD card in the board slot. You can now power-up the board by connecting the USB-C cable to the board, in CN6, PWR_IN and to your PC at the other end. Check that it boots your new bootloaders. You can verify this by checking the build dates:

```
U-Boot SPL 2021.01-00307-gd71be19902 (Jan 12 2021 - 10:02:03 +0000)

STM32MP>
```

In U-Boot, type the help command, and explore the few commands available.

Setting up Ethernet communication

Later on, we will transfer files from the development workstation to the board using the TFTP protocol, which works on top of an Ethernet connection.

To start with, install and configure a TFTP server on your development workstation, as detailed in the bootloader slides.

With a network cable, connect the Ethernet port labelled ETH0/GETH of your board to the one of your computer. If your computer already has a wired connection to the network, your instructor will provide you with a USB Ethernet adapter. A new network interface should appear on your Linux system.

Find the name of this interface by typing:

```
=> ip a
```

The network interface name is likely to be enxxx⁴. If you have a pluggable Ethernet device, it's easy to identify as it's the one that shows up after plugging in the device.

Then, instead of configuring the host IP address from NetWork Manager's graphical interface, let's do it through its command line interface, which is so much easier to use:

```
$ nmcli con add type ethernet ifname en... ip4 192.168.0.1/24
```

Now, configure the network on the board in U-Boot by setting the ipaddr and serverip environment variables:

⁴Following the *Predictable Network Interface Names* convention: <https://www.freedesktop.org/wiki/Software/systemd/PredictableNetworkInterfaceNames/>

```
=> setenv ipaddr 192.168.0.100
=> setenv serverip 192.168.0.1
```

To make these settings permanent, save the environment:

```
=> saveenv
```

You can then test the TFTP connection. First, put a small text file in the directory exported through TFTP on your development workstation. Then, from U-Boot, do:

```
=> tftp 0xc4000000 textfile.txt
```

The `tftp` command should have downloaded the `textfile.txt` file from your development workstation into the board's memory at location `0xc4000000`⁵.

You can verify that the download was successful by dumping the contents of the memory:

```
=> md 0xc4000000
```

We will see in the next labs how to use U-Boot to download, flash and boot a kernel.

Rescue binaries

If you have trouble generating binaries that work properly, or later make a mistake that causes you to lose your bootloader binaries, you will find working versions under `data/` in the current lab directory.

⁵ This location is part of the board DRAM. If you want to check where this value comes from, you can check the `stm32mp157` datasheet at https://www.st.com/resource/en/reference_manual/dm00327659.pdf. It's a big document (more than 4,000 pages). In this document, look for Memory organization and you will find the SoC memory map. You will see that the address range for the memory controller (*DDRC*) starts at `0xc0000000` and ends at `0xdfffffff`. This shows that the `0xc4000000` address is within the address range for RAM. You can also try with other values in the same address range.

Kernel sources

Objective: Learn how to get the kernel sources and patch them.

After this lab, you will be able to:

- Get the kernel sources from the official location
- Apply kernel patches

Setup

Create the `$HOME/embedded-linux-4d-labs/kernel` directory and go into it.

Get the sources

Go to the Linux kernel web site (<https://kernel.org/>) and identify the latest stable version.

Just to make sure you know how to do it, check the version of the Linux kernel running on your machine.

We will use `linux-5.10.x`, which this lab was tested with.

To practice with the `patch` command later, download the full 5.9 sources. Unpack the archive, which creates a `linux-5.9` directory.

Remember that you can use `wget <URL>` on the command line to download files.

Apply patches

Download the patch files corresponding to the latest 5.10 stable release: a first patch to move from 5.9 to 5.10 and if one exists, a second patch to move from 5.10 to 5.10.x.

Without uncompressing them to a separate file, apply the patches to the Linux source directory.

View one of the patch files with `vi` or `gvim` (if you prefer a graphical editor), to understand the information carried by such a file. How are described added or removed files?

Rename the `linux-5.9` directory to `linux-5.10.<x>`.

Kernel - Cross-compiling

Objective: Learn how to cross-compile a kernel for an ARM target platform.

After this lab, you will be able to:

- Set up a cross-compiling environment
- Cross compile the kernel for the STM32MP157A-DK1 Discovery kit
- Use U-Boot to download the kernel
- Check that the kernel you compiled starts the system

Setup

Go to the `$HOME/embedded-linux-4d-labs/kernel` directory.

Kernel sources

We will re-use the kernel sources downloaded and patched in the previous lab.

Cross-compiling environment setup

To cross-compile Linux, you need to have a cross-compiling toolchain. We will use the cross-compiling toolchain that we previously produced, so we just need to make it available in the `PATH`:

```
$ export PATH=$HOME/x-tools/arm-training-linux-uclibcgnueabiHF/bin:$PATH
```

Also, don't forget to either:

- Define the value of the `ARCH` and `CROSS_COMPILE` variables in your environment (using `export`)
- **Or** specify them on the command line at every invocation of `make`, i.e: `make ARCH=... CROSS_COMPILE=... <target>`

Linux kernel configuration

We could use the `multi_v7_defconfig` default configuration to build a working kernel but to save time and compile less code, we provide in `$HOME/embedded-linux-4d-labs/linux-stm32/` a minimal configuration file, named `stm32mp157_defconfig`. Copy it to `.config` and then run either `make olddefconfig` or `make oldconfig` if you want to get asked for all the possible choices.

Don't hesitate to visualize the new settings by running `make xconfig` afterwards!

In the kernel configuration, as an experiment, change the kernel compression from `Gzip` to `XZ`. This compression algorithm is far more efficient than `Gzip`, in terms of compression ratio, at the expense of a higher decompression time.

Cross compiling

At this stage, you need to install the `libssl-dev` package to compile the kernel.

You're now ready to cross-compile your kernel. Simply run:

```
$ make
```

and wait a while for the kernel to compile. Don't forget to use `make -j<n>` if you have multiple cores on your machine!

Look at the end of the kernel build output to see which file contains the kernel image. You can also see the Device Tree `.dtb` files which got compiled. Find which `.dtb` file corresponds to your board.

Copy the linux kernel image and DTB files to the TFTP server home directory.

Load and boot the kernel using U-Boot

As we are going to boot the Linux kernel from U-Boot, we need to set the `bootargs` environment corresponding to the Linux kernel command line:

```
=> setenv bootargs console=ttySTM0
```

We will use TFTP to load the kernel image on the board:

- On your workstation, copy the zImage and DTB (`stm32mp157a-dk1.dtb`) to the directory exposed by the TFTP server.
- On the target (in the U-Boot prompt), load zImage from TFTP into RAM:

```
=> tftp 0xc0000000 zImage
```

- Now, also load the DTB file into RAM:

```
=> tftp 0xc4000000 stm32mp157a-dk1.dtb
```

- Boot the kernel with its device tree:

```
=> bootz 0xc0000000 - 0xc4000000
```

You should see Linux boot and finally panicking. This is expected: we haven't provided a working root filesystem for our device yet.

You can now automate all this every time the board is booted or reset. Reset the board, and customize `bootcmd`:

```
=> setenv bootcmd 'tftp 0xc0000000 zImage; tftp 0xc4000000 stm32mp157a-dk1.dtb;  
bootz 0xc0000000- 0xc4000000'  
=> saveenv
```

Restart the board to make sure that booting the kernel is now automated.

Writing the kernel and DTB on the SD card

In order to let the kernel boot on the board autonomously, we can copy the kernel image and DTB in the boot partition we created previously.

Insert the SD card in your PC, it will get auto-mounted. Copy the kernel and device tree:

```
$ sudo cp arch/arm/boot/dts/stm32mp157a-dk1.dtb arch/arm/boot/zImage /media/\
training/boot/
$ sudo umount /dev/mmcblk0p4
```

Insert the SD card back in the board and reset it. You should now be able to load the DTB and kernel image from the SD card and boot with:

```
=> ext2load mmc 0:4 0xc0000000 zImage
=> ext2load mmc 0:4 0xc4000000 stm32mp157a-dk1.dtb
=> bootz 0xc0000000 - 0xc4000000
```

You are now ready to modify `bootcmd` to boot the board from SD card. But first, save the settings for booting from `tftp`:

```
=> setenv bootcmdtftp ${bootcmd}
```

This will be useful to switch back to `tftp` booting mode later in the labs.

Finally, using `editenv bootcmd`, adjust `bootcmd` so that the Discovery board starts using the kernel from the SD card.

Now, reset the board to check that it boots in the same way from the SD card. Check that this is really your own version of the kernel that's running⁶

⁶Look at the kernel log. You will find the kernel version number as well as the date when it was compiled. That's very useful to check that you're not loading an older version of the kernel instead of the one that you've just compiled.

Tiny embedded system with Busy-Box

Objective: making a tiny yet full featured embedded system

After this lab, you will:

- be able to configure and build a Linux kernel that boots on a directory on your workstation, shared through the network by NFS.
- be able to create and configure a minimalistic root filesystem from scratch (ex nihilo, out of nothing, entirely hand made...) for your target board.
- understand how small and simple an embedded Linux system can be.
- be able to install BusyBox on this filesystem.
- be able to create a simple startup script based on `/sbin/init`.
- be able to set up a simple web interface for the target.

Lab implementation

While (s)he develops a root filesystem for a device, a developer needs to make frequent changes to the filesystem contents, like modifying scripts or adding newly compiled programs.

It isn't practical at all to reflash the root filesystem on the target every time a change is made. Fortunately, it is possible to set up networking between the development workstation and the target. Then, workstation files can be accessed by the target through the network, using NFS.

Unless you test a boot sequence, you no longer need to reboot the target to test the impact of script or application updates.

Setup

Go to the `$HOME/embedded-linux-4d-labs/tinysystem/` directory.

Kernel configuration

We will re-use the kernel sources from our previous lab, in `$HOME/embedded-linux-4d-labs/kernel/`.

In the kernel configuration built in the previous lab, verify that you have all options needed for booting the system using a root filesystem mounted over NFS. Also check that `CONFIG_DEVTMPFS_MOUNT` is enabled. If necessary, rebuild your kernel.

Setting up the NFS server

Create a `nfsroot` directory in the current lab directory. This `nfsroot` directory will be used to store the contents of our new root filesystem.

Install the NFS server by installing the `nfs-kernel-server` package if you don't have it yet. Once installed, edit the `/etc/exports` file as root to add the following line, assuming that the IP address of your board will be `192.168.0.100`:

```
/home/<user>/embedded-linux-4d-labs/tinysystem/nfsroot 192.168.0.100(rw,
no_root_squash,no_subtree_check)
```

Of course, replace `<user>` by your actual user name.

Make sure that the path and the options are on the same line. Also make sure that there is no space between the IP address and the NFS options, otherwise default options will be used for this IP address, causing your root filesystem to be read-only.

Then, restart the NFS server:

```
$ sudo service nfs-kernel-server restart
```

Booting the system

First, boot the board to the U-Boot prompt. Before booting the kernel, we need to tell it that the root filesystem should be mounted over NFS, by setting some kernel parameters.

So add settings to the `bootargs` environment variable, **in just 1 line**:

```
=> setenv bootargs "${bootargs} root=/dev/nfs ip=192.168.0.100::::eth0
nfsroot=192.168.0.1:/home/<user>/embedded-linux-4d-labs/tinysystem/nfsroot,
nfsvers=3,tcp rw
```

Once again, replace `<user>` by your actual user name.

Of course, you need to adapt the IP addresses to your exact network setup. Save the environment variables (with `saveenv`).

You will later need to make changes to the `bootargs` value. Don't forget you can do this with the `editenv` command.

Now, boot your system. The kernel should be able to mount the root filesystem over NFS:

```
VFS: Mounted root (nfs filesystem) on device 0:14.
```

If the kernel fails to mount the NFS filesystem, look carefully at the error messages in the console. If this doesn't give any clue, you can also have a look at the NFS server logs in `/var/log/syslog`.

However, at this stage, the kernel should stop because of the below issue:

```
[ 7.476715] devtmpfs: error mounting -2
```

This happens because the kernel is trying to mount the *devtmpfs* filesystem in */dev/* in the root filesystem. To address this, create a *dev* directory under *nfsroot* and reboot.

Now, the kernel should complain for the last time, saying that it can't find an init application:

```
Kernel panic - not syncing: No working init found. Try passing init= option to kernel. See Linux Documentation/admin-guide/init.rst for guidance.
```

Obviously, our root filesystem being mostly empty, there isn't such an application yet. In the next paragraph, you will add Busybox to your root filesystem and finally make it usable.

Root filesystem with Busybox

Download the sources of the latest BusyBox 1.33.x release.

To configure BusyBox, we won't be able to use `make xconfig`, which is currently broken for BusyBox in Ubuntu 20.04, because it requires an old version of the Qt library.

So, let's use `$ make menuconfig`.

Now, configure BusyBox with the configuration file provided in the *data/* directory (remember that the Busybox configuration file is *.config* in the Busybox sources).

If you don't use the BusyBox configuration file that we provide, at least, make sure you build BusyBox statically! Compiling Busybox statically in the first place makes it easy to set up the system, because there are no dependencies on libraries. Later on, we will set up shared libraries and recompile Busybox.

Build BusyBox using the toolchain that you used to build the kernel.

Going back to the BusyBox configuration interface specify the installation directory for BusyBox⁷. It should be the path to your *nfsroot* directory.

Now run `$ make install` to install BusyBox in this directory.

Try to boot your new system on the board. You should now reach a command line prompt, allowing you to execute the commands of your choice.

Virtual filesystems

Run the `$ ps` command. You can see that it complains that the */proc* directory does not exist. The `ps` command and other process-related commands use the *proc* virtual filesystem to get their information from the kernel.

From the Linux command line in the target, create the *proc*, *sys* and *etc* directories in your root filesystem.

Now mount the *proc* virtual filesystem. Now that */proc* is available, test again the `ps` command.

Note that you can also now halt your target in a clean way with the `halt` command, thanks to *proc* being mounted⁸.

⁷You will find this setting in Settings -> Install Options -> BusyBox installation prefix.

⁸`halt` can find the list of mounted filesystems in */proc/mounts*, and unmount each of them in a clean way before shutting down.

System configuration and startup

The first user space program that gets executed by the kernel is `/sbin/init` and its configuration file is `/etc/inittab`.

In the BusyBox sources, read details about `/etc/inittab` in the [examples/inittab](#) file.

Then, create a `/etc/inittab` file and a `/etc/init.d/rcS` startup script declared in `/etc/inittab`. In this startup script, mount the `/proc` and `/sys` filesystems.

Any issue after doing this?

Starting the shell in a proper terminal

Before the shell prompt, you probably noticed the below warning message:

```
/bin/sh: can't access tty; job control turned off
```

This happens because the shell specified in the `/etc/inittab` file in started by default in `/dev/console`:

```
::askfirst:/bin/sh
```

When nothing is specified before the leading `::`, `/dev/console` is used. However, while this device is fine for a simple shell, it is not elaborate enough to support things such as job control (`[Ctrl][c]` and `[Ctrl][z]`), allowing to interrupt and suspend jobs.

So, to get rid of the warning message, we need `init` to run `/bin/sh` in a real terminal device:

```
ttySTM0::askfirst:/bin/sh
```

Reboot the system and the message will be gone!

Switching to shared libraries

Take the `hello.c` program supplied in the lab `data` directory. Cross-compile it for ARM, dynamically-linked with the libraries⁹, and run it on the target.

You will first encounter a very misleading `not found` error, which is not because the `hello` executable is not found, but because something else is not found using the attempt to execute this executable. What's missing is the `ld-uClibc.so.0` executable, which is the dynamic linker required to execute any program compiled with shared libraries. Using the `find` command (see examples in your command memento sheet), look for this file in the toolchain install directory, and copy it to the `lib/` directory on the target.

Then, running the executable again and see that the loader executes and finds out which shared libraries are missing.

If you still get the same error message, work, just try again a few seconds later. Such a delay can be needed because the NFS client can take a little time (at most 30-60 seconds) before seeing the changes made on the NFS server.

Similarly, find the missing libraries in the toolchain and copy them to `lib/` on the target.

Once the small test program works, we are going to recompile Busybox without the static compilation option, so that Busybox takes advantages of the shared libraries that are now present on the target.

⁹Invoke your cross-compiler in the same way you did during the toolchain lab

Before doing that, measure the size of the `busybox` executable.

Then, build Busybox with shared libraries, and install it again on the target filesystem. Make sure that the system still boots and see how much smaller the `busybox` executable got.

Implement a web interface for your device

Replicate `data/www/` to the `/www` directory in your target root filesystem.

Now, run the BusyBox http server from the target command line:

```
=> /usr/sbin/httpd -h /www/
```

It will automatically background itself.

If you use a proxy, configure your host browser so that it doesn't go through the proxy to connect to the target IP address, or simply disable proxy usage. Now, test that your web interface works well by opening `http://192.168.0.100` on the host.

See how the dynamic pages are implemented. Very simple, isn't it?

Going further

If you have time before the others complete their labs...

Initramfs booting

Configure your kernel to include the contents of the `nfsroot` directory as an initramfs.

Before doing this, you will need to create an `init` link in the toplevel directory to `sbin/init`, because the kernel will try to execute `/init`. You will also need to mount `devtmpfs` from the `rcS` script, it cannot be mounted automatically by the kernel when you're booting from an initramfs.

Note: you won't need to modify your `root=` setting in the kernel command line. It will just be ignored if you have an initramfs.

Filesystems - Block file systems

Objective: configure and boot an embedded Linux system relying on block storage

After this lab, you will be able to:

- Manage partitions on block storage.
- Produce file system images.
- Configure the kernel to use these file systems
- Use the tmpfs file system to store temporary files

Goals

After doing the *A tiny embedded system* lab, we are going to copy the filesystem contents to the SD card. The filesystem will be split into several partitions, and your Discovery kit will be booted with this SD card, without using NFS anymore.

Setup

Throughout this lab, we will continue to use the root filesystem we have created in the `$HOME/embedded-linux-4d-labs/tinysystem/nfsroot` directory, which we will progressively adapt to use block filesystems.

Filesystem support in the kernel

Recompile your kernel with support for SquashFS and ext4¹⁰.

Update your kernel image in the boot partition.

Boot your board with this new kernel and on the NFS filesystem you used in this previous lab.

Now, check the contents of `/proc/filesystems`. You should see that ext4 and SquashFS are now supported.

Add partitions to the SD card

We're going to use the SD card for our block device.

Plug the SD card in your workstation. If partitions are mounted, unmount them:

```
$ sudo umount /dev/mmcblk0p*
```

Using `parted`, add two partitions, starting from the beginning of the remaining space, with the following properties:

¹⁰Basic configuration options for these filesystems will be sufficient. No need for things like extended attributes.

- One partition, 2 MB big.
- One partition, that fills the rest of the SD card, that will be used for the data filesystem.

Use `quit` when you are done.

Data partition on the SD card

Using the `mkfs.ext4` create a journaled file system on the sixth partition of the SD card:

```
$ sudo mkfs.ext4 -L data -E nodiscard /dev/mmcb1k0p6
```

- `-L` assigns a volume name to the partition
- `-E nodiscard` disables bad block discarding. While this should be a useful option for cards with bad blocks, skipping this step saves long minutes in SD cards.

Now, mount this new partition and move the contents of the `/www/upload/files` directory (in your target root filesystem) into it. The goal is to use the data partition of the SD card as the storage for the uploaded images.

Insert the SD card in your board and boot. You should see the partitions in `/proc/partitions`.

Mount this sixth partition on `/www/upload/files`.

Once this works, modify the startup scripts in your root filesystem to do it automatically at boot time.

Reboot your target system and with the `mount` command, check that `/www/upload/files` is now a mount point for the sixth SD card partition. Also make sure that you can still upload new images, and that these images are listed in the web interface.

Adding a tmpfs partition for log files

For the moment, the upload script was storing its log file in `/www/upload/files/upload.log`. To avoid seeing this log file in the directory containing uploaded files, let's store it in `/var/log` instead.

Add the `/var/log/` directory to your root filesystem and modify the startup scripts to mount a `tmpfs` filesystem on this directory. You can test your `tmpfs` mount command line on the system before adding it to the startup script, in order to be sure that it works properly.

Modify the `www/cgi-bin/upload.cfg` configuration file to store the log file in `/var/log/upload.log`. You will lose your log file each time you reboot your system, but that's OK in our system. That's what `tmpfs` is for: temporary data that you don't need to keep across system reboots.

Reboot your system and check that it works as expected.

Making a SquashFS image

We are going to store the root filesystem in a SquashFS filesystem in the fifth partition of the SD card.

In order to create SquashFS images on your host, you need to install the `squashfs-tools` package. Now create a SquashFS image of your NFS root directory.

Finally, using the `dd` command, copy the file system image to the fifth partition of the SD card.

Booting on the SquashFS partition

In the U-boot shell, configure the kernel command line to use the fifth partition of the SD card as the root file system. Also add the `rootwait` boot argument, to wait for the SD card to be properly initialized before trying to mount the root filesystem. Since the SD cards are detected asynchronously by the kernel, the kernel might try to mount the root filesystem too early without `rootwait`.

Check that your system still works. Congratulations if it does!

Third party libraries and applications

Objective: Learn how to leverage existing libraries and applications: how to configure, compile and install them

To illustrate how to use existing libraries and applications, we will extend the small root filesystem built in the *A tiny embedded system* lab to add the *ALSA* libraries and tools and an audio playback application using the *ALSA* libraries. *ALSA* stands for (*Advanced Linux Sound Architecture*), and is the Linux audio subsystem.

We'll see that manually re-using existing libraries is quite tedious, so that more automated procedures are necessary to make it easier. However, learning how to perform these operations manually will significantly help you when you face issues with more automated tools.

Audio support in the Kernel

Recompile your kernel with audio support. The options we want are: [CONFIG_SOUND](#), [CONFIG_SND](#), [CONFIG_SND_USB](#) and [CONFIG_SND_USB_AUDIO](#).

At this stage, the easiest solution to update your kernel is probably to get back to copying it to RAM from tftp. Anyway, we will have to modify U-Boot environment variables, as we are going to switch back to NFS booting anyway.

Make sure that your board still boots with this new kernel.

Figuring out library dependencies

We're going to integrate the *alsa-utils* and *ogg123* executables. As most software components, they in turn depend on other libraries, and these dependencies are different depending on the configuration chosen for them. In our case, the dependency chain for *alsa-utils* is quite simple, it only depends on the *alsa-lib* library.

The dependencies are a bit more complex for *ogg123*. It is part of *vorbis-tools*, that depend on *libao* and *libvorbis*. *libao* in turn depends on *alsa-lib*, and *libvorbis* on *libogg*.

libao, *alsa-utils* and *alsa-lib* are here to abstract the use of *ALSA*. *vorbis-tools*, *libvorbis* and *libogg* are used to handle the audio files encoded using the Ogg container and Vorbis codec, which are quite common.

So, we end up with the following dependency tree:

Of course, all these libraries rely on the C library, which is not mentioned here, because it is already part of the root filesystem built in the *A tiny embedded system* lab. You might wonder how to figure out this dependency tree by yourself. Basically, there are several ways, that can be combined:

- Read the library documentation, which often mentions the dependencies;
- Read the help message of the `configure` script (by running `./configure --help`).
- By running the `configure` script, compiling and looking at the errors.

To configure, compile and install all the components of our system, we're going to start from the bottom of the tree with *alsa-lib*, then continue with *alsa-utils*, *libao*, *libogg*, and *libvorbis*, to finally compile *vorbis-tools*.

Preparation

For our cross-compilation work, we will need two separate spaces:

- A *staging* space in which we will directly install all the packages: non-stripped versions of the libraries, headers, documentation and other files needed for the compilation. This *staging* space can be quite big, but will not be used on our target, only for compiling libraries or applications;
- A *target* space, in which we will only copy the required files from the *staging* space: binaries and libraries, after stripping, configuration files needed at runtime, etc. This target space will take a lot less space than the *staging* space, and it will contain only the files that are really needed to make the system work on the target.

To sum up, the *staging* space will contain everything that's needed for compilation, while the *target* space will contain only what's needed for execution.

So, in `$HOME/embedded-linux-4d-labs/thirdparty`, create two directories: `staging` and `target`.

For the target, we need a basic system with BusyBox and initialization scripts. We will re-use the system built in the *A tiny embedded system* lab, so copy this system in the target directory:

```
$ cp -a $HOME/embedded-linux-4d-labs/tinysystem/nfsroot/* target/
```

Note that for this lab, a lot of typing will be required. To save time typing, we advise you to copy and paste commands from the electronic version of these instructions.

Testing

Make sure the `target/` directory is exported by your NFS server to your board by modifying `/etc/exports` and restarting your NFS server.

Make your board boot from this new directory through NFS.

alsa-lib

`alsa-lib` is a library supposed to handle the interaction with the ALSA subsystem. It is available at <https://alsa-project.org>. Download version 1.2.3.2 (there's an issue in version 1.2.4 for the moment), and extract it in `$HOME/embedded-linux-4d-labs/thirdparty/`.

Tip: if the website for any of the source packages that we need to download in the next sections is down, a great mirror that you can use is <http://sources.buildroot.net/>.

Back to `alsa-lib` sources, look at the `configure` script and see that it has been generated by `autoconf` (the header contains a sentence like *Generated by GNU Autoconf 2.69*). Most of the time, `autoconf` comes with `automake`, that generates Makefiles from `Makefile.am` files. So `alsa-lib` uses a rather common build system. Let's try to configure and build it:

```
$ ./configure
$ make
```

You can see that the files are getting compiled with `gcc`, which generates code for x86 and not for the target platform. This is obviously not what we want, so we clean-up the object and tell the `configure` script to use the ARM cross-compiler:

```
$ make clean
$ CC=arm-linux-gcc ./configure
```

Of course, the `arm-linux-gcc` cross-compiler must be in your `PATH` prior to running the `configure` script. The `CC` environment variable is the classical name for specifying the compiler to use.

Quickly, you should get an error saying:

```
checking whether we are cross compiling... configure: error: in `.../thirdparty/
alsa-lib-1.1.6':
configure: error: cannot run C compiled programs.
If you meant to cross compile, use `--host'.
See `config.log' for more details
```

If you look at the `config.log` file, you can see that the `configure` script compiles a binary with the cross-compiler and then tries to run it on the development workstation. This is a rather usual thing to do for a `configure` script, and that's why it tests so early that it's actually doable, and bails out if not.

Obviously, it cannot work in our case, and the script exits. The job of the `configure` script is to test the configuration of the system. To do so, it tries to compile and run a few sample applications to test if this library is available, if this compiler option is supported, etc. But in our case, running the test examples is definitely not possible.

We need to tell the `configure` script that we are cross-compiling, and this can be done using the `--build` and `--host` options, as described in the help of the `configure` script:

```
System types:
  --build=BUILD configure for building on BUILD [guessed]
```

```
--host=HOST cross-compile to build programs to run on HOST [BUILD]
```

The `--build` option allows to specify on which system the package is built, while the `--host` option allows to specify on which system the package will run. By default, the value of the `--build` option is guessed and the value of `--host` is the same as the value of the `--build` option. The value is guessed using the `./config.guess` script, which on your system should return `i686-pc-linux-gnu`. See https://www.gnu.org/software/autoconf/manual/html_node/Specifying-Names.html for more details on these options.

So, let's override the value of the `--host` option:

```
$ CC=arm-linux-gcc ./configure --host=arm-linux
```

The `configure` script should end properly now, and create a Makefile. Run the `make` command, which should run just fine.

Look at the result of compiling in `src/.libs`: a set of object files and a set of `libasound.so*` files.

The `libasound.so*` files are a dynamic version of the library. The shared library itself is `libasound.so.2.0.0`, it has been generated by the following command line:

```
$ arm-linux-gcc -shared conf.o confmisc.o input.o output.o async.o error.o \  
  dlmisc.o socket.o shmarea.o userfile.o names.o -lm -ldl -lpthread -lrt -Wl,\  
  -soname -Wl,libasound.so.2 -o libasound.so.2.0.0
```

And creates the symbolic links `libasound.so` and `libasound.so.2`.

```
$ ln -s libasound.so.2.0.0 libasound.so.2  
$ ln -s libasound.so.2.0.0 libasound.so
```

These symlinks are needed for two different reasons:

- `libasound.so` is used at compile time when you want to compile an application that is dynamically linked against the library. To do so, you pass the `-llibname` option to the compiler, which will look for a file named `lib<LIBNAME>.so`. In our case, the compilation option is `-lasound` and the name of the library file is `libasound.so`. So, the `libasound.so` symlink is needed at compile time;
- `libasound.so.2` is needed because it is the *SONAME* of the library. *SONAME* stands for *Shared Object Name*. It is the name of the library as it will be stored in applications linked against this library. It means that at runtime, the dynamic loader will look for exactly this name when looking for the shared library. So this symbolic link is needed at runtime.

To know what's the *SONAME* of a library, you can use:

```
$ arm-linux-readelf -d libasound.so.2.0.0
```

and look at the `(SONAME)` line. You'll also see that this library needs the `C` library, because of the `(NEEDED)` line on `libc.so.0`.

The mechanism of *SONAME* allows to change the library without recompiling the applications linked with this library. Let's say that a security problem is found in the `alsa-lib` release that provides `libasound 2.0.0`, and fixed in the next `alsa-lib` release, which will now provide `libasound 2.0.1`.

You can just recompile the library, install it on your target system, change the `libasound.so.2` link so that it points to `libasound.so.2.0.1` and restart your applications. And it will work,

because your applications don't look specifically for `libasound.so.2.0.0` but for the *SONAME* `libasound.so.2`.

However, it also means that as a library developer, if you break the ABI of the library, you must change the *SONAME*: change from `libasound.so.2` to `libasound.so.3`.

Finally, the last step is to tell the `configure` script where the library is going to be installed. Most `configure` scripts consider that the installation prefix is `/usr/local/` (so that the library is installed in `/usr/local/lib`, the headers in `/usr/local/include`, etc.). But in our system, we simply want the libraries to be installed in the `/usr` prefix, so let's tell the `configure` script about this:

```
$ CC=arm-linux-gcc ./configure --host=arm-linux --disable-python --prefix=/usr
$ make
```

For this library, this option may not change anything to the resulting binaries, but for safety, it is always recommended to make sure that the prefix matches where your library will be running on the target system.

Do not confuse the *prefix* (where the application or library will be running on the target system) from the location where the application or library will be installed on your host while building the root filesystem.

For example, `libasound` will be installed in `$HOME/embedded-linux-4d-labs/thirdparty/target/usr/lib/` because this is the directory where we are building the root filesystem, but once our target system will be running, it will see `libasound` in `/usr/lib`.

The prefix corresponds to the path in the target system and **never** on the host. So, one should **never** pass a prefix like `$HOME/embedded-linux-4d-labs/thirdparty/target/usr`, otherwise at runtime, the application or library may look for files inside this directory on the target system, which obviously doesn't exist! By default, most build systems will install the application or library in the given prefix (`/usr` or `/usr/local`), but with most build systems (including *autotools*), the installation prefix can be overridden, and be different from the configuration prefix.

We now only have the installation process left to do.

First, let's make the installation in the *staging* space:

```
$ make DESTDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging install
```

Now look at what has been installed by `alsa-lib`:

- Some configuration files in `/usr/share/alsa`
- The headers in `/usr/include`
- The shared library and its `libtool (.la)` file in `/usr/lib`
- A `pkgconfig` file in `/usr/lib/pkgconfig`. We'll come back to these later

Finally, let's install the library in the *target* space:

1. Create the `target/usr/lib` directory, it will contain the stripped version of the library
2. Copy the dynamic version of the library. Only `libasound.so.2` and `libasound.so.2.0.0` are needed, since `libasound.so.2` is the *SONAME* of the library and `libasound.so.2.0.0` is the real binary:

- `$ cp -a staging/usr/lib/libasound.so.2* target/usr/lib`
3. Measure the size of the `target/usr/lib/libasound.so.2.0.0` library before stripping.
 4. Strip the library:
 - `$ arm-linux-strip target/usr/lib/libasound.so.2.0.0`
 5. Measure the size of the `target/usr/lib/libasound.so.2.0.0` library again after stripping. How many unnecessary bytes were saved?

And we're done with `alsa-lib`!

Alsa-utils

Download `alsa-utils` from the ALSA official webpage. We tested the lab with version 1.2.4.

Once uncompressed, we quickly discover that the `alsa-utils` build system is based on the *autotools*, so we will work once again with a regular `configure` script.

As we've seen previously, we will have to provide the prefix and host options and the `CC` variable:

```
$ CC=arm-linux-gcc ./configure --host=arm-linux --prefix=/usr
```

Now, we should quickly get an error in the execution of the `configure` script:

```
checking for libasound headers version >= 1.0.27... not present.
configure: error: Sufficiently new version of libasound not found.
```

Again, we can check in `config.log` what the `configure` script is trying to do:

```
configure:7146: checking for libasound headers version >= 1.0.27
configure:7208: arm-linux-gcc -c -g -O2 confctest.c >&5
confctest.c:12:10: fatal error: alsa/asoundlib.h: No such file or directory
```

Of course, since *alsa-utils* uses *alsa-lib*, it includes its header file! So we need to tell the C compiler where the headers can be found: there are not in the default directory `/usr/include/`, but in the `/usr/include` directory of our *staging* space. The help text of the `configure` script says:

```
CPPFLAGS                C/C++/Objective C preprocessor flags,
                        e.g. -I<include dir> if you have headers
                        in a nonstandard directory <include dir>
```

Let's use it:

```
$ CPPFLAGS=-I$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/include \
  CC=arm-linux-gcc \
  ./configure --host=arm-linux --prefix=/usr
```

Now, it should stop a bit later, this time with the error:

```
checking for libasound headers version >= 1.0.27... found.
checking for snd_ctl_open in -lasound... no
configure: error: No linkable libasound was found.
```

The `configure` script tries to compile an application against *libasound* (as can be seen from the `-lasound` option): *alsa-utils* uses *alsa-lib*, so the `configure` script wants to make sure this library is already installed. Unfortunately, the `ld` linker doesn't find it. So, let's tell the linker where to look for libraries using the `-L` option followed by the directory where our libraries

are (in `staging/usr/lib`). This `-L` option can be passed to the linker by using the `LDFLAGS` at configure time, as told by the help text of the `configure` script:

```
LDFLAGS      linker flags, e.g. -L<lib dir> if you have
              libraries in a nonstandard directory <lib dir>
```

Let's use this `LDFLAGS` variable:

```
$ LDFLAGS=-L$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib \
  CPPFLAGS=-I$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/include \
  CC=arm-linux-gcc \
  ./configure --host=arm-linux --prefix=/usr
```

Once again, it should fail a bit further down the tests, this time complaining about a missing `curses helper header`. `curses` or `ncurses` is a graphical framework to design UIs in the terminal. This is only used by `alsamixer`, one of the tools provided by `alsa-utils`, that we are not going to use. Hence, we can just disable the build of `alsamixer`.

Of course, if we wanted it, we would have had to build `ncurses` first, just like we built `alsa-lib`. We will also need to disable support for `xmlto` that generates the documentation.

```
$ LDFLAGS=-L$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib \
  CPPFLAGS=-I$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/include \
  CC=arm-linux-gcc \
  ./configure --host=arm-linux --prefix=/usr \
  --disable-alsamixer --disable-xmlto
```

Then, run the compilation with `make`. Hopefully, it works!

Let's now begin the installation process. Before really installing in the staging directory, let's install in a dummy directory, to see what's going to be installed (this dummy directory will not be used afterwards, it is only to verify what will be installed before polluting the staging space):

```
$ make DESTDIR=/tmp/alsa-utils/ install
```

The `DESTDIR` variable can be used with all Makefiles based on `automake`. It allows to override the installation directory: instead of being installed in the configuration prefix directory, the files will be installed in `DESTDIR/configuration-prefix`.

Now, let's see what has been installed in `/tmp/alsa-utils/` (run `tree /tmp/alsa-utils`):

```
/tmp/alsa-utils/
|-- lib
|   |-- systemd
|   |   |-- system
|   |       |-- alsa-restore.service
|   |       |-- alsa-state.service
|   |       |-- sound.target.wants
|   |           |-- alsa-restore.service -> ../alsa-restore.service
|   |           |-- alsa-state.service -> ../alsa-state.service
|   |-- udev
|       |-- rules.d
|           |-- 89-alsa-ucm.rules
|           |-- 90-alsa-restore.rules
|-- usr
|   |-- bin
```

```
| | |-- aconnect

    |   |   |-- aconnect.1
    |   |   |-- alsabat.1
    |   |   |-- alsactl.1
    |   |   |-- alsa-info.sh.1
    |   |   |-- alsaloop.1
    |   |   |-- amidi.1
    |   |   |-- amixer.1
    |   |   |-- aplay.1
    |   |   |-- aplaymidi.1
    |   |   |-- arecord.1 -> aplay.1
    |   |   |-- arecordmidi.1
    |   |   |-- aseqdump.1
    |   |   |-- aseqnet.1
    |   |   `-- axfer.1
```

```

|         | | | |-- axfer-list.1
|         | | | |-- axfer-transfer.1
|         | | | |-- iecset.1
|         | | | `-- speaker-test.1
|         | | |-- man7
|         | | `-- man8
|         | `-- alsacnf.8
|     `-- sounds
|         `-- alsa
|             |-- Front_Center.wav
|             |-- Front_Left.wav
|             |-- Front_Right.wav
|             |-- Noise.wav
|             |-- Rear_Center.wav
|             |-- Rear_Left.wav
|             |-- Rear_Right.wav
|             |-- Side_Left.wav
|             `-- Side_Right.wav
|-- var
|   |-- lib
|     |-- alsa

```

24 directories, 63 files

So, we have:

- The systemd service definitions in `lib/systemd`
- The udev rules in `lib/udev`
- The alsa-utils binaries in `/usr/bin` and `/usr/sbin`
- Some sound samples in `/usr/share/sounds`
- The various translations in `/usr/share/locale`
- The manual pages in `/usr/share/man/`, explaining how to use the various tools
- Some configuration samples in `/usr/share/alsa`.

Now, let's make the installation in the *staging* space:

```
$ make DESTDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging/ install
```

Then, let's install only the necessary files in the *target* space, manually:

```

$ cd ..
$ cp -a staging/usr/bin/a* staging/usr/bin/speaker-test target/usr/bin/
$ cp -a staging/usr/sbin/alsa* target/usr/sbin
$ arm-linux-strip target/usr/bin/a*
$ arm-linux-strip target/usr/bin/speaker-test
$ arm-linux-strip target/usr/sbin/alsactl
$ mkdir -p target/usr/share/alsa/pcm
$ cp -a staging/usr/share/alsa/alsa.conf* target/usr/share/alsa/
$ cp -a staging/usr/share/alsa/cards target/usr/share/alsa/
$ cp -a staging/usr/share/alsa/pcm/default.conf target/usr/share/alsa/pcm/

```

And we're finally done with *alsa-utils*!

Now test that all is working fine by running the `speaker-test` util on your board, with the headset provided by your instructor plugged in. You may need to add the missing libraries from the toolchain install directory.

Caution: don't copy the `dmix.conf` file. `speaker-test` will tell you that it cannot find this file, but it won't work if you copy this file from the staging area.

The sound you get will be mainly noise (as what you would get by running `speaker-test` on your PCs). This is a way to test all possible frequencies, but is not really meant for a human to listen to. At least, sound output is showing some signs of life! It will get much better when we play samples with `ogg123`.

libogg

Now, let's work on *libogg*. Download the 1.3.4 version from <https://xiph.org> and extract it.

Configuring *libogg* is very similar to the configuration of the previous libraries:

```
$ CC=arm-linux-gcc ./configure --host=arm-linux --prefix=/usr
```

Of course, compile the library:

```
$ make
```

Installation to the *staging* space can be done using the classical `DESTDIR` mechanism:

```
$ make DESTDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging/ install
```

And finally, only install manually in the *target* space the files needed at runtime:

```
$ cd ..  
$ cp -a staging/usr/lib/libogg.so.0* target/usr/lib/  
$ arm-linux-strip target/usr/lib/libogg.so.0.8.4
```

Done with *libogg*!

libvorbis

Libvorbis is the next step. Grab the 1.3.7 version from <https://xiph.org> and uncompress it.

Once again, the *libvorbis* build system is a nice example of what can be done with a good usage of the autotools. Cross-compiling *libvorbis* is very easy, and almost identical to what we've seen with *alsa-utils*. First, the configure step:

```
$ CC=arm-linux-gcc ./configure --host=arm-linux --prefix=/usr
```

It will fail with:

```
configure: error: Ogg >= 1.0 required !
```

By running `./configure --help`, you will find the `--with-ogg-libraries` and `--with-ogg-includes` options. Use these:

```
$ CC=arm-linux-gcc ./configure --host=arm-linux --prefix=/usr \
```

```
--with-ogg-includes=$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/\
include \
--with-ogg-libraries=$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib
```

Then, compile the library:

```
$ make
```

Install it in the *staging* space:

```
$ make DESTDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging/ install
```

And install only the required files in the *target* space:

```
$ cd ..
$ cp -a staging/usr/lib/libvorbis.so.0* target/usr/lib/
$ arm-linux-strip target/usr/lib/libvorbis.so.0.4.9
$ cp -a staging/usr/lib/libvorbisfile.so.3* target/usr/lib/
$ arm-linux-strip target/usr/lib/libvorbisfile.so.3.3.8
```

And we're done with *libvorbis*!

libao

Now, let's work on *libao*. Download the 1.2.0 version from <https://xiph.org> and extract it.

Configuring *libao* is once again fairly easy, and similar to every sane autotools based build system:

```
$ LDFLAGS=-L$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib \
CPPFLAGS=-I$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/include \
CC=arm-linux-gcc ./configure --host=arm-linux --prefix=/usr
```

Of course, compile the library:

```
$ make
```

Installation to the *staging* space can be done using the classical DESTDIR mechanism:

```
$ make DESTDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging/ install
```

And finally, install manually the only needed files at runtime in the *target* space:

```
$ cd ..
$ cp -a staging/usr/lib/libao.so.4* target/usr/lib/
$ arm-linux-strip target/usr/lib/libao.so.4.1.0
```

We will also need the *alsa* plugin that is loaded dynamically by *libao* at startup:

```
$ mkdir -p target/usr/lib/ao/plugins-4/
$ cp -a staging/usr/lib/ao/plugins-4/libalsa.so target/usr/lib/ao/plugins-4/
```

Done with *libao*!

vorbis-tools

Finally, thanks to all the libraries we compiled previously, all the dependencies are ready. We can now build the vorbis tools themselves. Download the 1.4.2 version from the official website, at <https://xiph.org/>. As usual, extract the tarball.

Before starting the configuration, let's have a look at the available options by running `./configure --help`. Many options are available. We see that we can, in addition to the usual autotools configuration options:

- Enable/Disable the various tools that are going to be built: `ogg123`, `oggdec`, `oggenc`, etc.
- Enable or disable support for various other codecs: `FLAC`, `Speex`, etc.
- Enable or disable the use of various libraries that can optionally be used by the vorbis tools

So, let's begin with our usual configure line:

```
$ LDFLAGS=-L$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib \  
  CPPFLAGS=-I$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/include \  
  CC=arm-linux-gcc \  
  ./configure --host=arm-linux --prefix=/usr
```

At the end, you should see the following warning:

```
configure: WARNING: Prerequisites for ogg123 not met, ogg123 will be skipped.  
Please ensure that you have POSIX threads, libao, and (optionally) libcurl  
libraries and headers present if you would like to build ogg123.
```

Which is unfortunate, since we precisely want `ogg123`.

If you look back at the script output, you should see that at some point that it tests for `libao` and fails to find it:

```
checking for AO... no  
configure: WARNING: libao too old; >= 1.0.0 required
```

If you look into the `config.log` file now, you should find something like:

```
configure:22343: checking for AO  
configure:22351: $PKG_CONFIG --exists --print-errors "ao >= 1.0.0"  
Package ao was not found in the pkg-config search path.  
Perhaps you should add the directory containing 'ao.pc'  
to the PKG_CONFIG_PATH environment variable  
No package 'ao' found
```

In this case, the `configure` script uses the `pkg-config` system to get the configuration parameters to link the library against `libao`. By default, `pkg-config` looks in `/usr/lib/pkgconfig/` for `.pc` files, and because the `libao-dev` package is probably not installed in your system the `configure` script will not find `libao` library that we just compiled.

It would have been worse if we had the package installed, because it would have detected and used our host package to compile `libao`, which, since we're cross-compiling, is a pretty bad thing to do.

This is one of the biggest issue with cross-compilation: mixing host and target libraries, because build systems have a tendency to look for libraries in the default paths.

So, now, we must tell *pkg-config* to look inside the `/usr/lib/pkgconfig/` directory of our *staging* space. This is done through the `PKG_CONFIG_LIBDIR` environment variable, as explained in the manual page of *pkg-config*.

Moreover, the `.pc` files contain references to paths. For example, in `$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib/pkgconfig/ao.pc`, we can see:

```
prefix=/usr
exec_prefix=${prefix}
libdir=${exec_prefix}/lib
includedir=${prefix}/include
[...]
Libs: -L${libdir} -lao
Cflags: -I${includedir}
```

So we must tell *pkg-config* that these paths are not absolute, but relative to our *staging* space. This can be done using the `PKG_CONFIG_SYSROOT_DIR` environment variable.

Then, let's run the configuration of the *vorbis-tools* again, passing the `PKG_CONFIG_LIBDIR` and `PKG_CONFIG_SYSROOT_DIR` environment variables:

```
$ LDFLAGS=-L$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib \
  CPPFLAGS=-I$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/include \
  PKG_CONFIG_LIBDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging/usr/lib/\
  pkgconfig \
  PKG_CONFIG_SYSROOT_DIR=$HOME/embedded-linux-4d-labs/thirdparty/staging \
  CC=arm-linux-gcc \
  ./configure --host=arm-linux --prefix=/usr
```

Now, the *configure* script should end properly, we can now start the compilation:

```
$ make
```

It should fail with the following cryptic message:

```
make[2]: Entering directory '/home/tux/embedded-linux-4d-labs/thirdparty/
vorbis-tools-1.4.0/ogg123'
if arm-linux-gcc -DSYSCONFDIR=\"/usr/etc\" -DLOCALEDIR=\"/usr/share/locale\" -DHAVE
_CONFIG_H -I. -I. -I.. -I/usr/include -I../include -I../intl -I/home/tux/
embedded-linux-4d-labs/thirdparty/staging/usr/include -O2 -Wall -ffast-math
-fsigned-char -g -O2 -MT audio.o -MD -MP -MF ".deps/audio.Tpo" -c -o audio.o
audio.c; \
then mv -f ".deps/audio.Tpo" ".deps/audio.Po"; else rm -f ".deps/audio.Tpo"; exit
1; fi
In file included from audio.c:22:
/usr/include/stdio.h:27:10: fatal error: bits/libc-header-start.h: No such file or
directory
```

You can notice that `/usr/include` is added to the include paths. Again, this is not what we want because it contains includes for the host, not the target. It is coming from the autodetected value for `CURL_CFLAGS`.

Add the `--without-curl` option to the *configure* invocation, restart the compilation.

Finally, it builds!

Now, install the *vorbis-tools* to the *staging* space using:

```
$ make DESTDIR=$HOME/embedded-linux-4d-labs/thirdparty/staging/ install
```

And then install them in the *target* space:

```
$ cd ..  
$ cp -a staging/usr/bin/ogg* target/usr/bin  
$ arm-linux-strip target/usr/bin/ogg*
```

You can now test that everything works! Run `ogg123` on the sample file found in `thirdparty/data`.

There should still be one missing C library object. Copy it, and you should get: +

```
ERROR: Failed to load plugin /usr/lib/ao/plugins-4/libalsa.so => dlopen() failed  
=== Could not load default driver and no driver specified in config file. Exiting.
```

This error message is unfortunately not sufficient to figure out what's going wrong. It's a good opportunity to use the `strace` utility (covered in upcoming lectures) to get more details about what's going on. To do so, you can use the one built by `Crosstool-ng` inside the toolchain `target/usr/bin` directory.

You can now run `ogg123` through `strace`:

```
$ strace ogg123 /sample.ogg
```

You can see that the command fails to open the `ld-uClibc.so.1` file:

```
open("/lib/ld-uClibc.so.1", O_RDONLY) = -1 ENOENT (No such file or directory)  
open("/lib/ld-uClibc.so.1", O_RDONLY) = -1 ENOENT (No such file or directory)  
open("/usr/lib/ld-uClibc.so.1", O_RDONLY) = -1 ENOENT (No such file or directory)  
open("/usr/X11R6/lib/ld-uClibc.so.1", O_RDONLY) = -1 ENOENT (No such file or  
directory)  
open("/home/tux/embedded-linux-4d-labs/thirdparty/staging/usr/lib/ld-uClibc.so.1",  
O_RDONLY) = -1 ENOENT (No such file or directory)  
write(2, "ERROR: Failed to load plugin ", 29ERROR: Failed to load plugin ) = 29  
write(2, "/usr/lib/ao/plugins-4/libalsa.so", 32/usr/lib/ao/plugins-4/libalsa.so) =  
32  
write(2, " => dlopen() failed\n", 20 => dlopen() failed
```

Now, look for `ld-uClibc.so.1` in the toolchain. You can see that both `ld-uClibc.so.1` and `ld-uClibc.so.0` are symbolic links to the same file. So, create the missing link under `target/lib` and run `ogg123` again.

Everything should work fine now. Enjoy the sound sample!

To finish this lab completely, and to be consistent with what we've done before, let's strip the libraries in `target/lib`:

```
$ arm-linux-strip target/lib/*
```

Using a build system, example with Buildroot

Objectives: discover how a build system is used and how it works, with the example of the Buildroot build system. Build a Linux system with libraries and make it work on the board.

Setup

Create the `$HOME/embedded-linux-4d-labs/buildroot` directory and go into it.

Get Buildroot and explore the source code

The official Buildroot website is available at <https://buildroot.org/>. Download the latest stable 2021.02.<n> version which we have tested for this lab. Uncompress the tarball and go inside the Buildroot source directory.

Several subdirectories or files are visible, the most important ones are:

- `boot` contains the Makefiles and configuration items related to the compilation of common bootloaders (Grub, U-Boot, Barebox, etc.)
- `configs` contains a set of predefined configurations, similar to the concept of defconfig in the kernel.
- `docs` contains the documentation for Buildroot. You can start reading `buildroot.html` which is the main Buildroot documentation;
- `fs` contains the code used to generate the various root filesystem image formats
- `linux` contains the Makefile and configuration items related to the compilation of the Linux kernel
- `Makefile` is the main Makefile that we will use to use Buildroot: everything works through Makefiles in Buildroot;
- `package` is a directory that contains all the Makefiles, patches and configuration items to compile the user space applications and libraries of your embedded Linux system. Have a look at various subdirectories and see what they contain;
- `system` contains the root filesystem skeleton and the *device tables* used when a static `/dev` is used;
- `toolchain` contains the Makefiles, patches and configuration items to generate the cross-compiling toolchain.

Configure Buildroot

In our case, we would like to:

- Generate an embedded Linux system for ARM;
- Use an already existing external toolchain instead of having Buildroot generating one for us;
- Integrate *Busybox*, *alsa-utils* and *vorbis-tools* in our embedded Linux system;
- Integrate the target filesystem into a tarball

To run the configuration utility of Buildroot, simply run:

```
$ make menuconfig
```

Set the following options. Don't hesitate to press the **Help** button whenever you need more details about a given option:

- Target options
 - Target Architecture: ARM (little endian)
 - Target Architecture Variant: cortex-A7
 - Target ABI: EABIhf
 - Floating point strategy: VFPv4
- Toolchain
 - Toolchain type: External toolchain
 - Toolchain: Custom toolchain
 - Toolchain path: use the toolchain you built: `/home/<user>/x-tools/arm-training-linux-uclibcgnueabihf` (replace `<user>` by your actual user name)
 - External toolchain gcc version: 10.x
 - External toolchain kernel headers series: 5.10.x or later
 - External toolchain C library: uClibc/uClibc-ng
 - We must tell Buildroot about our toolchain configuration, so select Toolchain has WCHAR support?, Toolchain has SSP support? and Toolchain has C++ support?. Buildroot will check these parameters anyway.
- Target packages
 - Keep BusyBox (default version) and keep the Busybox configuration proposed by Buildroot;
 - Audio and video applications
 - * Select `alsa-utils`
 - * ALSA utils selection
 - Keep `alsactl`
 - Keep `alsamixer` (good to see, and needed to pull the `ncurses` dependency used in the next lab).
 - Select `speaker-test`
 - * Select `vorbis-tools`
- Filesystem images

- Select `tar` the root filesystem

Exit the menuconfig interface. Your configuration has now been saved to the `.config` file.

Generate the embedded Linux system

Just run:

```
$ make
```

Buildroot will first create a small environment with the external toolchain, then download, extract, configure, compile and install each component of the embedded system.

All the compilation has taken place in the `output/` subdirectory. Let's explore its contents:

- `build`, is the directory in which each component built by Buildroot is extracted, and where the build actually takes place
- `host`, is the directory where Buildroot installs some components for the host. As Buildroot doesn't want to depend on too many things installed in the developer machines, it installs some tools needed to compile the packages for the target. In our case it installed `pkg-config` (since the version of the host may be ancient) and tools to generate the root filesystem image (`genext2fs`, `makedevs`, `fakeroot`).
- `images`, which contains the final images produced by Buildroot. In our case it's just a tarball of the filesystem, called `rootfs.tar`, but depending on the Buildroot configuration, there could also be a kernel image or a bootloader image.
- `staging`, which contains the "build" space of the target system. All the target libraries, with headers and documentation. It also contains the system headers and the C library, which in our case have been copied from the cross-compiling toolchain.
- `target`, is the target root filesystem. All applications and libraries, usually stripped, are installed in this directory. However, it cannot be used directly as the root filesystem, as all the device files are missing: it is not possible to create them without being root, and Buildroot has a policy of not running anything as root.

Run the generated system

Go back to the `$HOME/embedded-linux-4d-labs/buildroot/` directory. Create a new `nfsroot` directory that is going to hold our system, exported over NFS. Go into this directory, and untar the `rootfs` using:

```
$ tar xvf ../buildroot-2021.02.<n>/output/images/rootfs.tar
```

Add our `nfsroot` directory to the list of directories exported by NFS in `/etc/exports`, and make sure the board uses it too.

Boot the board, and log in (root account, no password).

You should now have a shell, where you will be able to run `ogg123` like you used to in the previous lab.

Going further

- Add dropbear (SSH server and client) to the list of packages built by Buildroot and log to your target system using an ssh client on your development workstation. Hint: you will have to set a non-empty password for the root account on your target for this to work.
- Add a new package in Buildroot for the GNU Gtypist game. Read the Buildroot documentation to see how to add a new package. Finally, add this package to your target system, compile it and run it. The newest versions require a library that is not fully supported by Buildroot, so you'd better stick with the latest version in the 2.8 series.

Application development

Objective: Compile and run your own ncurses application on the target.

Setup

Go to the `$HOME/embedded-linux-4d-labs/appdev` directory.

Compile your own application

We will re-use the system built during the *Buildroot lab* and add to it our own application.

In the lab directory the file `app.c` contains a very simple *ncurses* application. It is a simple game where you need to reach a target using the arrow keys of your keyboard. We will compile and integrate this simple application to our Linux system.

Buildroot has generated toolchain wrappers in `output/host/usr/bin`, which make it easier to use the toolchain, since these wrappers pass some mandatory flags (especially the `--sysroot` `gcc` flag, which tells `gcc` where to look for the headers and libraries).

Let's add this directory to our `PATH`:

```
$ export PATH=$HOME/embedded-linux-4d-labs/buildroot/buildroot-2021.02.X/output/\
  host/usr/bin:$PATH
```

Let's try to compile the application:

```
$ arm-linux-gcc -o app app.c
```

It complains about undefined references to some symbols. This is normal, since we didn't tell the compiler to link with the necessary libraries. So let's use `pkg-config` to query the *pkg-config* database about the location of the header files and the list of libraries needed to build an application against *ncurses*¹¹:

```
$ arm-linux-gcc -o app app.c $(pkg-config --libs --cflags ncurses)
```

Our application is now compiled! Copy the generated binary to the NFS root filesystem (in the `root/` directory for example), start your system, and run your application!

You can also try to run it over `ssh` if you add `ssh` support to your target.

¹¹Again, `output/host/usr/bin` has a special `pkg-config` that automatically knows where to look, so it already knows the right paths to find `.pc` files and their `sysroot`.

Remote application debugging

Objective: Use `strace` to diagnose program issues. Use `gdbserver` and a cross-debugger to remotely debug an embedded application

Setup

Go to the `$HOME/embedded-linux-4d-labs/debugging` directory. Create an `nfsroot` directory.

Debugging setup

Because of issues in `gdb` and `ltrace` in the uClibc version that we are using in our toolchain, we will use a different toolchain in this lab, based on `glibc`.

As `glibc` has more complete features than lighter libraries, it looks like a good idea to do your application debugging work with a `glibc` toolchain first, and then switch to lighter libraries once your application and software stack is production ready.

Extract the Buildroot 2021.02.<n> sources into the current directory.

Then, in the `menuconfig` interface, configure the target architecture as done previously but configure the toolchain and target packages differently:

- In Toolchain:
 - Toolchain type: External toolchain
 - Toolchain: Bootlin toolchains
 - Toolchain origin: Toolchain to be downloaded and installed
 - Bootlin toolchain variant: `armv7-eabihf glibc stable 2020.08-1`
 - Select Copy gdb server to the Target
- Target packages
 - Debugging, profiling and benchmark
 - * Select `ltrace`
 - * Select `strace`

Now, build your root filesystem.

Go back to the `$HOME/embedded-linux-4d-labs/debugging` directory and extract the `buildroot-2021.02.<n>/output/images/rootfs.tar` archive in the `nfsroot` directory.

Add this directory to the `/etc/exports` file and restart `nfs-kernel-server`.

Boot your ARM board over NFS on this new filesystem, using the same kernel as before.

Using strace

Now, go to the `$HOME/embedded-linux-4d-labs/debugging` directory.

`strace` allows to trace all the system calls made by a process: opening, reading and writing files, starting other processes, accessing time, etc. When something goes wrong in your application, `strace` is an invaluable tool to see what it actually does, even when you don't have the source code.

Update the `PATH`:

```
$ export PATH=$HOME/embedded-linux-4d-labs/debugging/buildroot-2021.02.<n>/output\
/host/bin:$PATH
```

With your cross-compiling toolchain compile the `data/vista-emulator.c` program, strip it with `arm-linux-strip`, and copy the resulting binary to the `/root` directory of the root filesystem.

Back to target system, try to run the `/root/vista-emulator` program. It should hang indefinitely!

Interrupt this program by hitting `[Ctrl] [C]`.

Now, running this program again through the `strace` command and understand why it hangs. You can guess it without reading the source code!

Now add what the program was waiting for, and now see your program proceed to another bug, failing with a segmentation fault.

Using ltrace

Now run the program through `ltrace`.

Now you should see what the program does: it tries to consume as much system memory as it can!

Also run the program through `ltrace -c`, to see what function call statistics this utility can provide.

It's also interesting to run the program again with `strace`. You will see that memory allocations translate into `mmap()` system calls. That's how you can recognize them when you're using `strace`.

Using gdbserver

We are now going to use `gdbserver` to understand why the program segfaults.

Compile `vista-emulator.c` again with the `-g` option to include debugging symbols. This time, just keep it on your workstation, as you already have the version without debugging symbols on your target.

Then, on the target side, run `vista-emulator` under `gdbserver`. `gdbserver` will listen on a TCP port for a connection from `gdb`, and will control the execution of `vista-emulator` according to the `gdb` commands:

```
=> gdbserver localhost:2345 vista-emulator
```

On the host side, run `arm-linux-gdb` (also found in your toolchain):

```
$ arm-linux-gdb vista-emulator
```

`gdb` starts and loads the debugging information from the `vista-emulator` binary that has been compiled with `-g`.

Then, we need to tell where to find our libraries, since they are not present in the default `/lib` and `/usr/lib` directories on your workstation. This is done by setting the `gdb sysroot` variable (on one line):

```
(gdb) set sysroot /home/<user>/embedded-linux-4d-labs/debugging/\
      buildroot-2021.02.<n>/output/staging
```

Of course, replace `<user>` by your actual user name.

And tell `gdb` to connect to the remote system:

```
(gdb) target remote <target-ip-address>:2345
```

Then, use `gdb` as usual to set breakpoints, look at the source code, run the application step by step, etc. Graphical versions of `gdb`, such as `ddd` can also be used in the same way. In our case, we'll just start the program and wait for it to hit the segmentation fault:

```
(gdb) continue
```

You could then ask for a backtrace to see where this happened:

```
(gdb) backtrace
```

This will tell you that the segmentation fault occurred in a function of the C library, called by our program. This should help you in finding the bug in our application.

Post mortem analysis

Following the details in the slides, configure your shell on the target to get a core file dumped when you run `vista-emulator` again.

Once you have such a file, inspect it with `arm-linux-gdb` on the target, set the `sysroot` setting, and then generate a backtrace to see where the program crashed.

This way, you can have information about the crash without running the program through the debugger.

What to remember

During this lab, we learned that...

- It's easy to study the behavior of programs and diagnose issues without even having the source code, thanks to `strace` and `ltrace`.
- You can leave a small `gdbserver` program (about 300 KB) on your target that allows to debug target applications, using a standard `gdb` debugger on the development host.
- It is fine to strip applications and binaries on the target machine, as long as the programs and libraries with debugging symbols are available on the development host.
- Thanks to core dumps, you can know where a program crashed, without having to reproduce the issue by running the program through the debugger.
